

OPTICAL CROSS-CONNECT APPARATUS, AND
ITS SIGNAL MONITORING METHOD

BACKGROUND OF THE INVENTION

Field of the Invention

The present invention relates to an optical cross-connect apparatus for switching paths of light signals, and in particular, to an optical cross-connect apparatus for supervising quality and management information of light signals of which paths are switched and its signal supervising method.

Description of the Prior Art

An optical cross-connect system for switching paths of light signals transmitted into a system is equipped with an optical cross-connect apparatus (hereafter, abbreviated as OXC) having a light switch (Switch: hereafter, abbreviated as SW). It is possible to switch paths of large-capacity light signals by applying to this cross-connect system the wavelength division multiplex (hereafter, abbreviated as WDM) technology for multiplexing a plurality of signals of mutually different wavelength components. Various research and development on OXC equipped with optical SW are underway focusing attention on easiness of setting up a signal path, efficiency of protection and so on toward the information and communication age of increasingly larger-capacity (Chungpen

Fan, "Examining an integrated solution to optical transport networking.", Wavelength Division Multiplexing: (The first ever European meeting place for WDM Systems, Network, Marketing & Engineering Professionals), November 1997, London pp.

5 18-23).

FIG. 32 represents, as a concept, configuration of an optical cross-connect system to which such OXC is applied. An optical cross-connect system is equipped with a plurality of OXC, and is connected by an optical fiber transmission path on which light signals are mutually transmitted. Here, it has
10 OXC 10_1 to 10_6 , and for instance, OXC 10_1 is connected with OXC 10_2 via optical fiber transmission path 11_1 , with OXC 10_5 via optical fiber transmission path 11_5 , and with OXC 10_6 via optical fiber transmission path 11_6 respectively. Also, OXC
15 10_4 for instance is connected with OXC 10_3 via optical fiber transmission path 11_3 , with OXC 10_5 via optical fiber transmission path 11_4 , with OXC 10_6 via optical fiber transmission path 11_8 , and OXC 10_6 is connected with OXC 10_3 via optical fiber transmission path 10_7 respectively.

20 On operating an optical cross-connect system, in order to maintain the system reliability, it is necessary to supervise light signals that are switchable to various paths and manage transmission signals inside the system by each OXC as shown in FIG. 32. For instance, there are many transmission
25 paths for light signals transmitted from point A to point B. Therefore, each OXC supervises paths, quality states and so on of light signals, sets paths of light signals and avoids

failure occurrence points. To be more specific, in OXC 10₁, 10₆, 10₃ and 10₄, a service signal transmitted from point A to point B on path 12 indicated by dashed lines in FIG. 32 supervises transmitted light signals as to their respective
5 quality and management information 13₁, 13₂, 13₃ and 13₄ if included in them.

FIG. 33 represents an overview of conventional OXC for supervising quality and management information of such light signals. This OXC has light signal input terminals 20₁ to 20_n
10 (n is a natural number of 2 or more) to which light signals are inputted, n × n light SW21 for having light signals inputted from n pieces of input port corresponding to each of these light signal input terminals 20₁ to 20_n outputted from any one of n pieces of output port and switching their paths, light
15 signal detecting section (hereafter, abbreviated as DET) for detecting quality of light signals outputted from n pieces of output port of n × n light SW21 and management information included therein, light signal output terminals 23₁ to 23_n to which light signals outputted from each of n pieces of output
20 port of n × n light SW21 are outputted, light signal supervising section (hereafter, abbreviated as SV) 24 for supervising quality and management information of light signals from the output ports detected by DET 22₁ to 22_n, and control section (hereafter, abbreviated as CNT) 25 for controlling path
25 switching of n × n light SW21 from supervising results of SV24.

n × n light SW21 arbitrarily connects n pieces of input port with n pieces of output port according to a control signal

from CNT25. DET 22₁ to 22_n output light signals outputted from each output port of $n \times n$ light SW21 as-is and detect various signal states by branching a part of them. Such detecting functions of DET are a light signal level detecting function, a signal-to-noise (hereafter, abbreviated as SN) ratio detecting function, a light reproduction and overhead (hereafter, abbreviated as OH) detecting function, and a light reproduction and OH terminating function. As prescribed by the Synchronous Digital Hierarchy (hereafter, abbreviated as SDH) and the Synchronous Optical Network (hereafter, abbreviated as SONET) for instance, this OH has information on frame synchronization, error supervising, maintenance, operation and so on inserted in a predetermined position of light signals composed in a frame of a predetermined format.

15 In conventional OXC of such configuration, light signals inputted from light signal input terminals 20₁ to 20_n are inputted in n pieces of input port of $n \times n$ light SW21 respectively, and as a result of path switching performed according to a control signal from CNT25, they are outputted

20 from any one of n pieces of output port of $n \times n$ light SW21. And the light signals outputted from n pieces of output port of $n \times n$ light SW21 have their quality and management information included in them detected at DET 22₁ to 22_n respectively, and are also outputted from light signal output terminals 23₁ to

25 23_n. Such detected information is supervised at SV24, and SV24 instructs CNT25 to change path setting for instance from the results of supervising. CNT25 outputs a control signal

responding to this instruction from SV24 to $n \times n$ light SW21, and switches the path of light signals inputted from the input ports.

As a technology on OXC for supervising such light signals, in addition to this, the Japanese Patent Laid-Open No. 5-183509 "Light Switch and Optical Channel" for instance discloses a technology to perform path cutting or path setting for a light SW that supervises light signals branched on the one hand by a branching device provided per signal line and switches paths of light signals branched on the other hand by the branching device.

BRIEF SUMMARY OF THE INVENTION

Object of the Invention

However, the conventionally proposed OXC required DET for detecting information to be supervised from light signals for each one of n pieces of output port of a light SW, leading to larger size of OXC. Furthermore, as optical communication will increasingly spread and light signals will be of larger capacity, the number of ports of a light SW is destined to increase, and thus it becomes necessary to install additional DET to meet the increase, further leading to larger size and higher cost of OXC.

Thus, an object of the present invention is to provide OXC that is, even in the case where a light SW becomes large-seized, capable of supervising quality and management

information of light signals passing through inside the apparatus with low-cost configuration.

Summary of the Invention

In the present invention, an optical cross-connect apparatus includes: light switch means having n (n is a natural number of 2 or more) pieces of first port and at least $(n + 1)$ pieces of second port, which switches paths of light signals inputted from each of said first ports and has them outputted from any one of said second ports; light path control means for branching a path of said light switch means so as to have light signals inputted from any one of said first ports outputted from any two of said second ports; and light signal supervising means for supervising quality of light signals outputted from either of said two ports.

To be more specific, it includes light switch means having n pieces of first port and at least $(n + 1)$ pieces of second port, and by light path control means, it branches a path so as to have light signals inputted from any one of said first ports outputted from any two of said second ports. And by light signal supervising means, it supervises quality of light signals outputted from either of said two ports.

In the present invention, an optical cross-connect apparatus includes light switch means having n (n is a natural number of 2 or more) pieces of first port and at least $(n + 1)$ pieces of second port, which switches paths of light signals inputted from each of said first ports and has them outputted

from any one of said second ports, light path control means for branching a path of said light switch means so as to have light signals inputted from any one of said first ports outputted from any two of said second ports, light amplifying means for amplifying light signals outputted from either of said two ports, and light signal supervising means for supervising quality of light signals amplified by this light amplifying means.

To be more specific, the optical cross-connect apparatus includes light amplifying means for amplifying light signals outputted from the light switch means at a previous stage to the light signal supervising means. This can change a branching ratio between light signals to be supervised inputted in the light signal supervising means and signals outputted from the other second ports so that even if the levels of signals to be supervised become lower, the levels of light signals to be originally transmitted become correspondingly higher, and thus it allows an optical cross-connect apparatus of high reliability with a supervising function to be provided.

In the present invention, an optical cross-connect apparatus includes light switch means having a plurality of first and second ports, which switches paths of light signals inputted from each of said first ports and has them outputted from any one of said second ports, light path control means for branching a path of said light switch so as to have light signals inputted from any one of said first ports outputted from any two of said second ports when supervising said light

signals and have light signals inputted from each of said first ports outputted from predetermined one of said second ports when not supervising said light signal, and light signal supervising means for supervising quality of light signals
5 outputted from either of said two ports only when performing said supervising.

To be more specific, the present invention provides light switch means having a plurality of first and second ports, and by light path control means, it has light signals inputted
10 from any one of the first ports outputted from any two of the second ports when supervising light signal, and on the other hand, it has light signals inputted from each of the first ports outputted from predetermined one of the second ports when not supervising said light signal. And it supervises,
15 by light signal supervising means, quality of light signals outputted from either of said two ports only when performing supervising.

In the present invention, an optical cross-connect apparatus includes a wavelength separating means for
20 separating, per wavelength component, wavelength multiple light wherein light signals of a plurality of mutually different wavelength components are multiplexed, light switch means having n (n is a natural number of 2 or more) pieces of first port and at least $(n + 1)$ pieces of second port, which
25 switches light signals of the respective wavelength components separated by said wavelength separating means inputted from each of said first ports and has them outputted from any one

of said second ports, light path control means for branching
a path of said light switch means so as to have light signals
inputted from one of said first ports outputted from any two
of said second ports, light signal supervising means for
5 supervising quality of light signals outputted from a
predetermined third port of said two ports, wavelength
component converting means for converting each individual
light signal outputted from said second ports excluding said
third port into a light signal of predetermined wavelength
10 components, and wavelength multiplexing means for
multiplexing per predetermined number these light signals
converted by the wavelength component converting means.

To be more specific, the present invention provides an
input stage of light switch means for an optical cross-connect
15 apparatus with wavelength separating means for separating,
per wavelength component, wavelength multiple light wherein
light signals of a plurality of mutually different wavelength
components are multiplexed, and supervises light signals by
having a path of the light switch means branched by light path
20 control means, and on the other hand, it provides an output
stage of the light switch means with wavelength component
converting means for converting each individual light signal
outputted from any port other than a supervising port into
a light signal of predetermined wavelength components, and
25 it multiplexes a light signal of each of wavelength components
per predetermined unit by wavelength multiplexing means to
output them.

Moreover, in the present invention, an optical cross-connect apparatus is characterized by said light signal supervising means that detects and supervises management information placed in an overhead section of a predetermined frame format.

Moreover, in the present invention, the above optical cross-connect apparatus is characterized by said light path control means that sets a path for having light signals to be supervised inputted from each port outputted from said two ports per port in order.

Furthermore, in the present invention, an optical cross-connect apparatus includes light switch means having a plurality of first and second ports, which switches paths of light signals inputted from each of said first ports and has them outputted from any one of said second ports and also switches paths of light signals inputted from each of said second ports and has them outputted from any one of said first ports, n pieces of upward light signal input and output terminals, n pieces of downward light signal input and output terminals, a first light circulator provided corresponding to each of said first ports for outputting upward light signals inputted from each of the upward light signal input terminals to each corresponding port of said first ports and also outputting downward light signals inputted from each of said ports to said downward light signal output terminal, a second light circulator provided corresponding to each of said second ports for outputting downward light signals inputted from each

of the downward light signal input terminals to each corresponding port of said second ports and also outputting upward light signals inputted from each of said ports to said upward light signal output terminal, light path control means

5 for branching a path of said light switch means so as to have light signals inputted from any one of said first ports outputted from any two of said second ports and also have light signals inputted from any one of said second ports outputted from any two of said first ports, a first light signal

10 supervising means for supervising quality of light signals outputted from a predetermined third port of any two of said first ports, and a second light signal supervising means for supervising quality of light signals outputted from a predetermined fourth port of any two of said second ports.

15 To be more specific, the present invention provides each port of light switch means having a plurality of first and second ports with first and second light circulators, each of which performs two-way path switching of upward and downward light signals. And it has a path of light switch means branched
20 by the light path control means to have upward and downward light signals supervised by direction respectively by the light signal supervising means.

Moreover, in the present invention, an optical cross-connect apparatus is characterized by said first and
25 second light signal supervising means that detect and supervise management information placed in an overhead section of a predetermined frame format.

To be more specific, the present invention detects and supervises management information placed in an overhead section of a predetermined frame format, such as those prescribed by SDH and SONET.

5 Moreover, in the present invention, the optical cross-connect apparatus is characterized by said light path control means that sets a path for having light signals to be supervised inputted from any first or second port outputted from any two of said second or first ports per port in order.

10 To be more specific, as the paths of the light switch means are branched per port in order, the optical cross-connect apparatus can supervise light signals inputted from any port with one detecting means and one supervising means for supervising light signals even in the case where the apparatus
15 becomes large-sized with additional ports.

BRIEF DESCRIPTION OF THE DRAWINGS

This above-mentioned and other objects, features and advantages of this invention will become more apparent by reference to the following detailed description of the
20 invention taken in conjunction with the accompanying drawings, wherein:

FIG. 1 is a schematic diagram showing an example of configuration of an optical cross-connect system to which an OXC in a first embodiment of the present invention is applied;

25 FIG. 2 is a block diagram showing an example of configuration of nodes in the first embodiment;

FIG. 3 is a block diagram showing an overview of a configuration of the OXC in the first embodiment;

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Embodiments

The present invention will be described in detail as to embodiments hereafter.

5 First embodiment

FIG. 1 represents in schematic form an example of configuration of the optical cross-connect system to which OXC in the first embodiment of the present invention is applied. This optical cross-connect system is equipped with offices
10 (nodes) having OXC respectively, and is connected by an optical fiber transmission path on which light signals are mutually transmitted. Here, nodes 30_1 to 30_5 transmit light signals via fiber transmission paths 31_1 to 31_7 . For instance, node 30_1 is connected with node 30_2 via optical fiber transmission
15 path 31_1 , with node 30_5 via optical fiber transmission path 31_5 , and with node 30_3 via optical fiber transmission path 31_6 respectively. Also, node 30_4 for instance is connected with node 30_3 via optical fiber transmission path 31_3 , with node 30_5 via optical fiber transmission path 31_4 , with node
20 30_2 via optical fiber transmission path 31_7 respectively. Moreover, node 30_2 for instance is connected with node 30_3 via optical fiber transmission path 31_2 . In such an optical cross-connect system, paths are switched at each node, and such switched light signals are transmitted between nodes.
25 Thus, it becomes possible, by path setting of a light SW of OXC on each node, to have light signals transmitted in the system arbitrarily transmitted.

FIG. 2 represents an example of configuration of the nodes shown in FIG. 1. Here, it only shows configuration of node 30₁ on the assumption that nodes 30₁ to 30₅ have the same configuration. Node 30₁ has OXC321 in the first embodiment and optical transmitters 33₁ to 33₄. The input port of OXC321 is connected with optical fiber transmission path 34₁ on which light signals from the nodes which are other offices are transmitted and optical transmitters 33₁ and 33₂. The output port of OXC321 is connected with optical fiber transmission path 34₂ on which light signals to be outputted to the nodes which are other offices are transmitted and optical transmitters 33₃ and 33₄. For optical fiber transmission paths 34₁ and 34₂, there are optical fiber transmission paths 31₁, 31₆ and 31₅ connected with nodes 30₂, 30₃ and 30₅ which are other offices shown in FIG. 1. OXC 321 is equipped with a light SW, and the input port and the output port of OXC 321 are connected according to path setting of this light SW, and it allows quality and management information and so on of light signals passing through inside OXC 321 to be supervised.

FIG. 3 represents an overview of configuration of OXC in the first embodiment. The OXC in the first embodiment has n pieces of light signal input terminals 40₁ to 40_n, n pieces of light signal output terminals 41₁ to 41_n, and n × m light SW 42 (m is a natural number of 2 or more). Here, m is "n + 1." n pieces of input port of n × m light SW 42 are connected to light signal input terminals 40₁ to 40_n respectively, and n pieces out of m pieces of output port of n × m light SW 42

are connected to light signal output terminals 41_1 to 41_n respectively.

In addition, this OXC is equipped with light signal detecting section (DET) 43 for detecting quality and management information of light signals outputted from the remaining one piece of output port of $n \times m$ light SW42, light signal supervising section (SV) 44 for supervising quality and management information of light signals detected by DET 43, and light path control section (CNT) 45 for generating a control signal for switching a path of $n \times m$ light SW42 based on supervising results of SV 44.

$n \times m$ light SW42 switches paths of light signals inputted from light signal input terminals 40_1 to 40_n and has them outputted from any of light signal output terminals 41_1 to 41_n according to a control signal from CNT 45. $n \times m$ light SW42 can arbitrarily connect n pieces of input port with n pieces of output port according to this control signal, and this path setting allows light signals inputted from light signal input terminals 40_1 to 40_n to be outputted from any of light signal output terminals 41_1 to 41_n . In addition, at that time, $n \times m$ light SW42 in the first embodiment is characterized by having light signals inputted from any one input port simultaneously outputted from two ports in a connected state called a branch connection and having one of the two output ports outputted to an output port to which DET 43 is connected.

Such $n \times m$ light SW42 is comprised of an optical wave-guiding path and switch elements formed on a board of which materials are LiNbO_3 (lithium [naobate]) or quartz base. As for switch elements, it has 2×2 switch elements of which combination can easily implement 4×4 light SW, 8×8 light SW, and 32×32 light SW.

FIG. 4 represents an example of configuration of 4×4 light SW implemented by LiNbO_3 . The 4×4 light SW has light signals inputted from input port section 50 having four input ports outputted from any of the four output ports of output port section 52 by combination of 2×2 light SW 51. Each 2×2 light SW can switch paths by a control signal, and has light signals outputted from an arbitrary output port by combination of this path switching.

FIG. 5 represents an example of configuration of 8×8 light SW implemented by LiNbO_3 . The 8×8 light SW has light signals inputted from input port section 53 having eight input ports outputted from any of the eight output ports of output port section 55 by combination of 2×2 light SW 54. Each 2×2 light SW can switch paths by a control signal, and has light signals outputted from an arbitrary output port by combination of this path switching.

FIG. 6 represents an example of configuration of 32×32 light SW implemented by LiNbO_3 . The 32×32 light SW has light signals inputted from input port section 56 having thirty-two input ports inputted to a 4×8 light SW group in which eight pieces of 4×8 light SW 57 configured likewise

by combination of 2×2 light SW are arranged. These outputs are inputted to a 8×8 light SW group in which eight pieces of 8×8 light SW 58 configured as above-mentioned are arranged. In addition, these outputs of the 8×8 light SW group are
5 inputted to a 8×4 light SW group in which eight pieces of 8×4 light SW 59 configured likewise by combination of 2×2 light SW are arranged, and these outputs are outputted from any of the thirty-two pieces of output port of output port section 60. Each light SW can switch paths by a control signal,
10 and has light signals outputted from an arbitrary output port by combination of this path switching.

While $n \times m$ light SW42 has one more output port than input ports since it has a port to which DET 43 is connected as a supervising output port, it can be implemented likewise by
15 combining 2×2 switch elements in spite of such configuration.

CNT 25 in the first embodiment switches paths of $n \times m$ light SW42 by a control signal, and is capable of having the above-mentioned branch connection performed according to applied voltage value given as this control signal.

20 FIG. 7 represents an example of switching characteristics of 8×8 light SW. Here, it shows switching characteristics in the case where the paths of light signals of input port No. "1" in input port section 53 of 8×8 light SW shown in FIG. 5 are set to output port No. "1" to "8" in output port
25 section 55. The horizontal axis shows the applied voltage value from -10 volts (hereafter, abbreviated as V) to 70V applied as a control signal from CNT 45. Also, the vertical axis shows

the relative optical power value (unit: dB) of light signal power outputted from output port No. "1" or "8" that is a target switching path with reference to light signal power inputted to input port No. "1."

5 Relative optical power value 61 outputted from output port No. "1" indicates that the lower the applied voltage is, the higher the outputted optical level becomes and that it is outputted by power equivalent to that of the inputted light signals. In addition, relative optical power value 62 of light
10 signals outputted from output port No. "8" indicates that the higher the applied voltage is, the higher the outputted optical level becomes and that it is outputted by power equivalent to that of the inputted light signals. Thus, if attention is focused on light signals outputted from both output ports,
15 it means that applied voltage V_1 at which light signals outputted from output port No. "1" are in an "on" state and light signals outputted from output port No. "8" are in an "off" state, namely the lowest level, is the applied voltage capable of control that is most suitable to path switching
20 from input port No. "1" to output port No. "1." Likewise, it means that applied voltage V_2 at which light signals outputted from output port No. "8" are in an "on" state and light signals outputted from output port No. "1" are in an "off" state, namely the lowest level, is the applied voltage V_2 capable of control
25 that is most suitable to path switching from input port No. "1" to output port No. "8."

Applied voltage V_3 at which relative optical power value 61 outputted from output port No. "1" matches up with relative optical power value 62 outputted from output port No. "8" has light signals mutually attenuated just by 3dB against light signals inputted from input port No. "1" outputted from output ports No. "1" and "8" respectively. This state, as a branch connection state, is simultaneously outputted from the two output ports.

DET 43 in the first embodiment detects various states of light signals outputted from an output port predetermined as a supervising output port out of $n \times m$ light SW42 output ports. Such functions of DET are a light signal level detecting function, an optical SN ratio detecting function and an OH supervising function, for instance.

FIG. 8 represents an overview of configuration of DET in case of having a light signal level detecting function. This DET has light signals inputted from light signal input terminal 65 and inputted to photodiode (hereafter, abbreviated as PD) 66. PD 66 generates a photoelectric current of a size corresponding to a light reception level of the inputted light signals. The photoelectric current generated by PD 66 is supplied to current-voltage conversion circuit 67.

Current-voltage conversion circuit 67 generates voltage of a value corresponding to the supplied photoelectric current, and outputs it as an optical level detection value to optical level detection value output terminal 68.

DET of such configuration is used in order to detect an optical level of light signals of which paths were switched by $n \times m$ light SW42 in a branch state on PD66 and current-voltage conversion circuit 67 and supervise whether the level of light signals has become a desired level after passing $n \times m$ light SW42.

FIG. 9 represents an overview of configuration of DET in case of having an optical SN ratio detecting function. This DET has light signals inputted from light signal input terminal 69 and inputted to light signal SN ratio detecting circuit 70. Light signal SN ratio detecting circuit 70 detects a light signal SN ratio that is a ratio between a signal level and a noise level of inputted light signals. A light signal SN ratio detected by light signal SN ratio detecting circuit 70 is outputted as a light signal SN ratio detection value from light signal SN ratio detection value output terminal 71.

DET of such configuration is used in order to detect an SN ratio of light signals of which paths were switched by $n \times m$ light SW42 in a branch state on light signal SN ratio detecting circuit 70 and supervise quality of light signals after passing $n \times m$ light SW42.

FIG. 10 represents an overview of configuration of DET in case of having an OH detecting function. This DET has light signals inputted from light signal input terminal 72 and supplied to optical-electrical conversion circuit (hereafter, abbreviated as O/E) 73. O/E 73 converts inputted light signals to electric signals of values corresponding to the light signal

levels, and supplies them to overhead detecting circuit
(hereafter, abbreviated as OHDET) 74. OHDET 74 detects OH
placed in a predetermined position of a signal configured in
a frame of a predetermined format, and outputs it as header
5 information to header information output terminal 75.

DET of such configuration converts the light signals of
which paths were switched by $n \times m$ light SW42 in a branch
connection state to digital electric signals once, and
supervises header information, bit errors and so on included
10 therein. For instance, it can detect OH prescribed by SDH,
SONET and so on and supervise management information and a
quality state of light signals as the entire system.

The functions of DET 43 in the first embodiment are not
limited to the light signal level detecting function, light
15 signal SN ratio detecting function and OH supervising function
shown in FIG. 8 to 10. It is also possible for DET 43 to have
these functions in advance and adequately select one according
to system configuration and a type of light signals to be
transmitted.

20 CNT 45 is capable of promptly performing failure
management for $n \times m$ light SW42 such as changing a path of
specific light signals on detecting their break and so on from
supervising results of SV 44 in compliance with instructions
from SV 44 that supervised the above-mentioned detection
25 results by DET 43, and also capable of supervising light signals
passing through $n \times m$ light SW42. Thus, CNT 45 sequentially
performs branch connection to each of light signals to be

supervised at $n \times m$ light SW42 and has them inputted in DET 43. CNT 45 capable of such control has an unillustrated central processing unit (CPU), and it can perform the above-mentioned control according to a control program stored in a
5 predetermined storage device such as read only memory (ROM).

FIG. 11 represents an overview of processing contents of supervising control by CNT 45. CNT 45 first uses variable i indicating an input port number of $n \times m$ light SW42 to be supervised, and initializes this variable i to "1" (step S80).

10 To be more specific, as an initial state, it sets as a subject of supervising a first service signal, namely a light signal inputted from input port number "1" of $n \times m$ light SW42. Next, CNT 45 provides $n \times m$ light SW42 with a control signal equivalent to applied voltage V_3 as shown in FIG. 7 so that the i -th service
15 signal, namely a light signal from input port number " i " will be outputted from an output port of an output port number of a predetermined path and an output port of output port number " m " in a state of branch connection (step S81).

And DET43 detects quality and management information of
20 the i -th service signal outputted from output port number " m " and SV44 supervises it (step S82). If supervising does not end (step S83: N), it returns to step S82 and continues supervising. When supervising ends (step S83: Y), it adds "1" to variable i (step S84). It determines whether variable i
25 is larger than n that is the number of output ports excluding output port number " m ," namely a port for supervising $n \times m$ light SW42 (step S85), and if variable i is equal to or less

than n (step S85: N), it performs branch connection to the next service signal again in step S84 (step S81). If variable i is larger than n in step S85 (step S85: Y), it returns to S80 again (return).

5 Next, operation of OXC in such first embodiment will be concretely described by referring to FIGS. 12 and 13.

FIG. 12 represents, as a concept, a branch connection state when OXC in the first embodiment has the first service signal to be supervised. However, as to the portions that are
10 the same as the OXC shown in FIG. 3, the same symbols are given and description is omitted. Here, it is assumed that path setting is performed in advance so that the first service signal inputted from light signal input terminal 40_1 corresponding to input port number "1" of $n \times m$ light SW42 is outputted from
15 light signal output terminal 41_2 corresponding to output port number "2" of $n \times m$ light SW42. Likewise, it is assumed that path setting is performed in advance so that the second and n -th service signals 88 and 89 inputted from light signal input terminals 40_2 , 40_n corresponding to input port numbers "2,"
20 " n " of $n \times m$ light SW42 are outputted from light signal output terminals 41_n , 41_1 corresponding to output port numbers " n ," "1" of $n \times m$ light SW42.

In the case where the first service signal is to be supervised, path setting is performed for $n \times m$ light SW42
25 by CNT 45 so that first service signal 90 is simultaneously outputted from output port numbers "2," " m " of $n \times m$ light SW42 (branch connection state). This branch connection state

allows the first service signal to be outputted from light
signal output terminal 41₂, and also allows quality and
management information of the first service signal to be
detected at DET 43 and supervised at SV 44. Moreover, as the
5 second and n-th service signals are outputted as-is from light
signal output terminal of which a path is set, there is no
influence on other service signals so that only the supervision
subject service signals can be supervised. If supervising of
this first service signal is completed, CNT 45 changes paths
10 of n × m light SW42 so as to make the second service signal
a subject of supervising next.

FIG. 13 represents, as a concept, a branch connection
state when the OXC in the first embodiment has the second service
signal to be supervised. However, the same symbols are given
15 and description is omitted as to the portions that are the
same as FIG. 12. In the case where the second service signal
is to be supervised, n × m light SW42 switches a path of first
service signal 91 to predetermined output port number "2" of
n × m light SW42, and switches a path of the n-th service signal
20 89 to predetermined output port number "1" of n × m light SW42.

Path setting is performed so that second service signal
92 is simultaneously outputted from output port numbers "n,"
"m" of n × m light SW42 (branch connection state). This branch
connection state allows the second service signal to be
25 outputted from light signal output terminal 41_n, and also allows
quality and management information of the second service signal
to be detected at DET 43 and supervised at SV 44. If supervising

of this second service signal is completed, CNT 45 changes paths of $n \times m$ light SW42 so that the third service signal becomes a subject of supervising next. Hereafter, it changes paths likewise up to the n -th service signal and repeatedly
5 supervises all the service signals.

In the meantime, as already described, while a branch connection state can be implemented easily to $n \times m$ light SW42 in the first embodiment by a control signal equivalent to applied voltage V_3 shown in FIG. 7, it is important not to
10 deteriorate a service signal to be supervised so as to allow such supervision. Thus, what influence a branch connection state in a light SW exerts on a service signal to be supervised will be described next.

FIG. 14 represents a response waveform on switching a
15 branch connection of a 8×8 light SW implemented by LiNbO_3 . Here, a light signal inputted from input port number "1" shows output waveform 100 of a light signal outputted from output port number "1" and output waveform 101 of a light signal outputted from output port number "8" by an 8×8 light SW.
20 If attention is paid to output port number "1," these output waveforms indicate the response waveforms shown when the output light signal changes in the three states of an "on" state, a branch state and an "off" state in order. As also shown in FIG. 7, when an output light signal from output port number
25 "1" is in an "on" state, an output light signal from output port number "8" is in an "off" state. And in a branch state, output light signals are outputted from output port numbers

"1," "8." In addition, when an output light signal from output port number "1" is in an "off" state, an output light signal from output port number "8" is in an "on" state.

At the time of changing in the three states as above,
5 the states can be changed without interrupting the output light signals accompanying the path changes.

Also, regarding a code error rate accompanying switching of a branch connection, its characteristics can be measured by the following configuration so as to grasp the extent to
10 which the code error rate deteriorates compared with a case of performing no branch connection state.

FIG. 15 represents an overview of a system for measuring a code error rate accompanying switching of a branch connection. Here, a code error rate of a payload section into which a user
15 signal prescribed by SONET is inserted is measured, as to a measurement light signal (PN₂₃₁₋₁) wherein pseudo noise (hereafter, abbreviated as PN) is given per 2₃₁₋₁ bit to a light signal having transmission speed of 10 gigabits per second (Gbps) of optical carrier level 192 (hereafter, abbreviated
20 as OC-192) prescribed by SONET. This measurement system has a measurement electric signal transmitted from OC-192 transmitter (Tx) 105 converted into a light signal at E/O106 and inputted in input port number "1" of 8 × 8 light SW107. 8 × 8 light SW107 repeats path switching for two states, such
25 as a "branch connection state," output from output port number 1, a "branch connection state," and output from output port number 1, by a control signal outputted from transmitter 108

by switch control section (SWCNT) 109 in a cycle of 10 kilohertz (kHz). The measurement light signal outputted from output port number "1" of 8 × 8 light SW107 has its output level adjusted by variable attenuator (ATT) 110 and converted into an electric
5 signal by O/E 111 and then received by OC-192 receiver 112. A code error rate is measured as to the measurement light signal of measurement point 113 of O/E 111.

FIG. 16 represents an overview of signal power of a measurement light signal measured at a measurement point of
10 the measurement system shown in FIG. 15. The measurement light signal at the measurement point of the measurement shown in system FIG. 15 alternately repeats per 0.05 millisecond (ms) normal switching state 120 outputting from output port number "1" and branch connection state 121. In the case of performing
15 a branch connection at applied voltage V_3 shown in FIG. 7, light signal power of a measurement light signal in branch connection state 121 is approximately a half of signal power of a measurement light signal in normal switching state 120 as shown in FIG. 16. Here, an average of signal power of a
20 measurement light signal in branch connection state 121 is measured as average light reception power P_r (unit: dBm).

FIG. 17 represents an example of code error rate characteristics accompanying branch connection switching in an 8 × 8 light SW measured by the measurement system shown
25 in FIG. 15. The vertical axis shows a code error rate, and the horizontal axis shows average light reception power P_r (dBm). Also, as shown in FIG. 15, code error rate 130

(measurement point "○") in case of repeatedly switching a branch connection is indicated together with code error rate 131 (measurement point "●") in case of performing no branch connection. Thus, a measurement light signal makes little
5 difference between the case of not switching a light SW and the case of repeatedly switching a path in a branch connection in a light SW. To be more specific, it means that, even in case of repeatedly switching a path in a branch connection in a light SW, quality of a service signal equivalent to a
10 measurement light signal will not deteriorate.

Thus, as explained in FIGS. 14 to 17, it is possible, understandably, to supervise the service signals to be supervised by a branch connection hardly causing deterioration of quality.

15 The OXC in the first embodiment for supervising light signals by the above-mentioned branch connection can also be applied to a large-capacity transmission network system using WDM technology apart from the optical cross-connect systems of configuration shown in FIGS. 1 and 2.

20 FIG. 18 represents, as a concept, an example of configuration of a transmission network system using WDM technology to which the OXC in the first embodiment is applied. This network system is equipped with offices (nodes) 135₁ to 135₅ having OXC in the first embodiment respectively, and is
25 connected by optical fiber transmission paths 136₁ to 136₇ on which light signals are mutually transmitted. On each of optical fiber transmission paths, wavelength multiple light

signals having wavelength components λ_1 to λ_w (w is a natural number of 2 or more) are transmitted switching their paths at each node. Each node has OXC 137₅ in the first embodiment, light transmitting apparatuses 138₁ to 138₄ and wavelength dividing multiple separators 139₁ to 139₄. In wavelength dividing multiple separators 139₁ and 139₂, wavelength multiple light signals from each of nodes which are other offices are inputted and are separated into light signals of the wavelength components λ_1 to λ_w . These separated light signals of the wavelength components and the light signals from light transmitting apparatuses 138₁ and 138₂ are supplied to an input port of OXC 137₅. From the output port of OXC 137₅, as mentioned above, the light signals to which path switching was performed are inputted to wavelength dividing multiple separators 139₃ and 139₄ and light transmitting apparatuses 138₃ and 138₄. Wavelength dividing multiple separators 139₃ and 139₄ multiplex light signals of the wavelength components λ_1 to λ_w and outputs them to the nodes of other offices.

Thus, OXC 137₅ sets an arbitrary transmission path by performing path setting per wavelength component, and also supervises quality, management information and so on of light signals passing through inside the OXC 137₅. And WDM is used for connections with other nodes so as to perform large-capacity transmission to an arbitrary node.

As described above, the OXC in the first embodiment performs a branch connection at $n \times m$ light SW42 for each of the light signals inputted from n pieces of input port between

any one of n pieces of output port and a predetermined supervising port in order following a control signal from CNT 45. And it detects quality and management information from the light signals outputted from the supervising output port at DET43 and supervises it at SV44. As its supervision is performed one by one in a branch state even when there are a plurality of service signals to be supervised passing through the OXC, it requires only one signal detecting means and only one supervising means for the purpose of supervising the service signals, and thus it allows the OXC to be rendered smaller-sized and lower-cost. It is also possible, by performing a branch connection, to supervise not only the service signals not to be supervised but also the service signals to be supervised without influencing the quality.

Second embodiment

The OXC in the first embodiment was described as one wherein CNT 45 gives applied voltage V_3 as shown in FIG. 7 to $n \times m$ light SW 42 as a control signal so that light signals inputted from input port number "1" are attenuated by 3dB respectively and simultaneously outputted from output port numbers "1," "m." As opposed to this, the OXC in the second embodiment amplifies light signals outputted from a supervising output port of $n \times m$ light SW 42 by an amplifier once, and it thus performs its supervising function to low-level light signals outputted from the supervising output port.

FIG. 19 represents an overview of configuration of the OXC in such second embodiment. The OXC in the second embodiment has n pieces of light signal input terminal 140_1 to 140_n , n pieces of light signal output terminal 141_1 to 141_n and $n \times m$ light SW142. Here, m is " $n + 1$." n pieces of input ports of $n \times m$ light SW142 are connected to light signal input terminal 140_1 to 140_n respectively, and n pieces out of m pieces of output ports of $n \times m$ light SW142 are connected to light signal output terminal 141_1 to 141_n respectively. In addition, this OXC has light amplifier 143 for amplifying light signals outputted from the remaining one piece of output port of $n \times m$ light SW142, DET 144 for detecting quality and management information of light signals amplified by this light amplifier 143, SV145 for supervising quality and management information of light signals detected by DET 144, and CNT 146 for generating a control signal for switching a path of $n \times m$ light SW142 based on supervising results of SV 145.

Description is omitted as to configuration and operation of $n \times m$ light SW142, DET 144 and SV 145 in the second embodiment since they are the same as $n \times m$ light SW42, DET 43 and SV 44 in the first embodiment.

While the OXC in the second embodiment is the same as the first embodiment as to the processing flow of supervising by CNT 146, the voltage value of applied voltage that is a control signal to be given to $n \times m$ light SW142 is different. As for this OXC, when light signals inputted from an input port of $n \times m$ light SW142 are put in a branch connection state

according to a control signal, the branching ratio of these light signals is set so that the level of service signals outputted to light signal output terminal 141₁ to 141_n becomes higher. Along with this, the level of light signals to be supervised outputted from a supervising port becomes lower. Because of this, the OXC in the second embodiment amplifies the light signals outputted from a supervising port of $n \times m$ light SW142 by the light amplifier 143, and then detects various states of light signals amplified by DET 144.

A control signal from CNT 146 that allows such a branch connection will be described by taking as an example the switching characteristics of 8×8 light SW shown in FIG. 7.

FIG. 20 represents the concept of branching ratio setting in the example of 8×8 light SW switching characteristics shown in FIG. 7. As for the OXC in the first embodiment, as a voltage value equivalent to applied voltage V_3 is given to a light SW as a control signal, the levels of light signals outputted from output port numbers "1," "m" are equivalent, and light signals are supervised without deteriorating the characteristics of a code error rate. However, there are cases where precision is required as to this control signal. Thus, as for the OXC in the second embodiment, a voltage value equivalent to applied voltage V_4 is given to a light SW as a control signal.

If a voltage value equivalent to applied voltage V_4 is given to a light SW, relative optical power value 61 outputted from output port number "1" of an 8×8 light SW, for instance,

has higher output level, that is, from P_0 to P_1 in the first embodiment. On the other hand, relative optical power value 62 outputted from output port number "8" of the 8×8 light SW, for instance, has lower output level, that is, from P_0 to P_2 in the first embodiment. As for setting a branching ratio of a branch connection, $n \times m$ light SW142 can set it at an arbitrary level ratio by deviating it from applied voltage V_3 . Thus, it is possible to keep the levels of service signals as high as possible while supervising their quality and management information by DET 144, by amplifying light signals to be supervised at a rate of amplification corresponding to the level ratio set here by the light amplifier 143.

FIG. 21 represents, as a concept, a branch connection state when the OXC in the second embodiment has the first service signal to be supervised. However, as to the portions that are the same as the OXC shown in FIG. 19, the same symbols are given and description is omitted. Here, it is assumed that path setting is performed in advance so that the first service signal inputted from light signal input terminal 140_1 corresponding to input port number "1" of $n \times m$ light SW142 is outputted from light signal output terminal 141_2 corresponding to output port number "2" of $n \times m$ light SW142. Likewise, it is assumed that path setting is performed in advance so that the second and n -th service signals 150 and 151 inputted from light signal input terminals 140_2 , 140_n corresponding to input port numbers "2," "n" of $n \times m$ light SW142 are outputted from light signal output terminals 141_n ,

141₁ corresponding to output port numbers "n," "1" of n × m light SW142.

In the case where the first service signal is to be supervised, path setting is performed for n × m light SW142 by CNT 146 so that first service signal 15₂ is simultaneously outputted from output port numbers "2," "m" of n × m light SW142 (branch connection state). In this branch connection state, it is possible for the first service signal outputted from output port number "2" to be outputted from light signal output terminal 141₂, and it is also possible for part of the first service signal outputted from output port number "m" to be amplified by light amplifier 14₃ to a predetermined level once, and then for its quality and management information to be detected at DET 144 and supervised at SV 145. Moreover, as the second and n-th service signals are outputted as-is from the light signal output terminal of which a path is set, only the service signals to be supervised can be supervised with no influence on other service signals. Here, a branching ratio in a branch connection state is set so that the level of the first signal outputted from output port number "2" is sufficiently higher than the level of a light signal to be supervised as a part of the first signal outputted from output port number "m," and thus it is possible to supervise its quality and so on hardly lowering the level of service signals so as to further improve reliability.

Thus, as for the OXC in the second embodiment, when n × m light SW142 is put in a branch connection state by CNT

146, the branching ratio is set so that the light signals to be supervised will be sufficiently small, and on the other hand, the branched light signals to be supervised will be amplified once by light amplifier 14, and then its quality and management information will be supervised. Thus, it hardly lowers the level of service signals to be originally transmitted, and its function of supervising quality and so on remains intact so that reliability can be further improved.

Third embodiment

As for the OXC in the first and second embodiments, a supervising output port is assigned to a light SW in order to constantly supervise quality and so on of service signals transmitted in the apparatus. As opposed to this, as for the OXC in the third embodiment, when not supervising service signals, a supervising output port assigned to a light SW accommodates service signals of low priority for instance, just as other output ports do.

FIG. 22 represents an overview of configuration of the OXC in the third embodiment. The OXC in the third embodiment has m pieces of light signal input terminal 160_1 to 160_m , m pieces of light signal output terminal 161_1 to 161_m and $m \times m$ light SW162. In addition, this OXC has DET 163 for detecting quality and management information of light signals outputted from output port number "m" of $m \times m$ light SW162 and having light signals outputted as-is to light signal output terminal 161_m on the other hand, SV 164 for supervising quality and management information of light signals detected by DET 163,

and CNT 165 for generating a control signal for switching path setting of $m \times m$ light SW162 based on supervising results of SV 164.

While $m \times m$ light SW162 has one more input port than $n \times m$ light SW42 in the first embodiment, its operation is essentially the same. Also, SV 164 in the third embodiment is the same as SV 44 in the first embodiment. As opposed to this, DET163 in the third embodiment has a function of detecting a state of light signals and so on outputted from output port number "m" of $m \times m$ light SW162 and also a function of outputting light signals as-is. This detecting function of DET 163 includes a light signal level detecting function, optical SN ratio detecting function, a light reproduction and OH detecting function, a light reproduction and OH terminating function for instance. CNT 165 performs the same supervising process as CNT 45 in the first embodiment, and when not performing a supervising process, it has service signals of low priority outputted from output port number "m" of $m \times m$ light SW162 outputted as-is to light signal output terminal 161_m.

FIG. 23 represents an overview of configuration of DET in the third embodiment in case of having a light signal level detecting function. This DET has light signals inputted from input terminal 170 and branched in two by light coupler 171. One of the two branched by light coupler 171 is outputted as-is from output terminal 172. The other of the two branched by light coupler 171 is inputted to PD 173. PD 173 generates a photoelectric current of a size corresponding to a light

reception level of the inputted branch light. The photoelectric current generated by PD 173 is supplied to current-voltage conversion circuit 174. Current-voltage conversion circuit 174 generates voltage of a value corresponding to the supplied photoelectric current, and outputs it as an optical level detection value to optical level detection value output terminal 175.

DET of such configuration is used in order to branch part of light signals of which paths were switched by a light SW, detect the optical level of branched light on PD 173 and current-voltage conversion circuit 174, and supervise whether the level of light signals has become a desired level after passing the light SW.

FIG. 24 represents an overview of configuration of DET in the third embodiment in case of having an optical SN ratio detecting function. Such a DET has light signals inputted from input terminal 176 and branched in two by light coupler 177. One of the two branched by light coupler 177 is outputted as-is from output terminal 178. The other of the two branched by light coupler 171 is inputted to light signal SN ratio detecting circuit 179. Light signal SN ratio detecting circuit 179 detects a light signal SN ratio that is a ratio between a signal level and a noise level of inputted branch light. A light signal SN ratio detected by light signal SN ratio detecting circuit 179 is outputted as a light signal SN ratio detection value to light signal SN ratio detection value output terminal 180.

DET of such configuration is used in order to branch part of light signals of which paths were switched by light SW, detect an SN ratio of branch light on light signal SN ratio detecting circuit 179 and supervise quality of light signals after passing the light SW.

FIG. 25 represents an overview of configuration of DET in the third embodiment in case of having a light reproduction function and an OH detecting function. This DET has light signals having wavelength component λ_a inputted from input terminal 181 and supplied to O/E 182. O/E 182 converts inputted light signals to electric signals of values corresponding to the light signal levels, and supplies them to E/O 183 and OHDET 184. E/O 183 converts them to light signals having wavelength component λ_x at levels corresponding to the levels of supplied electric signals and outputs them to output terminal 185. OHDET 184 detects OH placed in a predetermined position of a signal configured in a frame of a predetermined format, and outputs it as header information to header information output terminal 186.

DET of such configuration converts the light signals of which paths were switched by a light SW to digital electric signals once, electrically improves their SN ratio and converts them again into light signals to send them out, and also supervises header information, bit errors and so on included in the digital electric signals. For instance, it can detect OH prescribed by SDH, SONET and so on and supervise management information and a quality state of light signals as the entire

system. Moreover, from the aspect of its reproducing function, it is used, for instance, as a reproducing apparatus in inter-office long-distance transmission or in case of converting a wavelength component of a light signal from λ_a to λ_x between input and output.

FIG. 26 represents an overview of configuration of DET in the third embodiment in case of having a light reproduction function and an OH terminating function. This DET has light signals having wavelength component λ_a inputted from input terminal 187 and supplied to O/E 188. O/E 188 converts inputted light signals to electric signals of values corresponding to the light signal levels, and supplies them to OH TeRMinal (hereafter, abbreviated as TRM) 189. OH TRM section 189 detects OH placed in a predetermined position of a signal configured in a frame of a predetermined format, and outputs it as header information to header information output terminal 190 and also reconfigures OH and supplies it to E/O 191 after terminating OH once. E/O 191 converts them into light signals having wavelength component λ_x at levels corresponding to the levels of supplied electric signals and outputs them to output terminal 192.

DET of such configuration converts light signals of which paths were switched by a light SW to digital electric signals once, electrically improves the SN ratio and then converts them again into light signals to send them out, and also supervises header information, bit errors and so on included in the digital electric signals. For instance, it can detect

OH prescribed by SDH, SONET and so on and supervise management information and a quality state of light signals as the entire system. In addition, OH TRM section 189 terminates OH and also reconfigures OH so as to enhance a function of managing the network. Moreover, from the aspect of its reproducing function, it is used, for instance, as a reproducing apparatus in inter-office long-distance transmission or in case of converting a wavelength component of a light signal from λ_a to λ_x between input and output.

The functions of DET 163 in the third embodiment are not limited to the light signal level detecting function, light signal SN ratio detecting function, light reproduction and OH detecting function, and light reproduction and OH terminating function shown in FIGS. 23 to 26. It is also possible for DET 163 to have these various functions in advance and adequately select one according to system configuration and a type of light signals to be transmitted.

Next, operation of OXC in such third embodiment will be concretely described by referring to FIG. 27 and 28.

FIG. 27 represents, as a concept, a branch connection state when the OXC in the third embodiment has the first service signal to be supervised. However, as to the portions that are the same as the OXC shown in FIG. 22, the same symbols are given and description is omitted. Here, it is assumed that path setting is performed in advance so that the first service signal inputted from light signal input terminal 160₁ corresponding to input port number "1" of $m \times m$ light SW 162

is outputted from light signal output terminal 161_2 corresponding to output port number "2" of $m \times m$ light SW162.

In the case where the first service signal is to be supervised, path setting is performed for $m \times m$ light SW162 by CNT 165 so that first service signal 195 is simultaneously outputted from output port numbers "2," "m" of $m \times m$ light SW162 (branch connection state). This branch connection state allows the first service signal to be outputted from light signal output terminal 161_2 , and also allows quality and management information of the first service signal to be detected at DET 163 and supervised at SV 164. In the case of continuing supervision, if supervising of the first service signal is completed as with the first embodiment, CNT 165 changes paths of $m \times m$ light SW162 so as to make the second service signal a subject of supervising next. However, when such supervising is not performed, CNT 165 of the OXC in the third embodiment can have service signals of low priority inputted from light signal input terminal 160_m outputted as-is from light signal output terminal 161_m .

FIG. 28 represents, as a concept, a connection state when the OXC in the third embodiment does not perform supervision. However, as to the portions that are the same as the OXC shown in FIG. 22, the same symbols are given and description is omitted. To be more specific, path switching is performed in advance so that the first service signal 196 inputted from light signal input terminal 160_1 corresponding to input port number "1" of $m \times m$ light SW162 is outputted from light signal output

terminal 161_2 corresponding to output port number "2" of $m \times m$ light SW162, and on the other hand, the m -th service signal 197 of low priority inputted from light signal input terminal 160_m corresponding to input port number " m " of $m \times m$ light SW162 is outputted from output port number " m " of $m \times m$ light SW162 and is outputted as-is from light signal output terminal 161_m via DET 163.

Thus, the OXC in the third embodiment has one more input port than the OXC in the first embodiment so as to output as-is from a light signal output terminal when supervising is not performed, so it can accommodate service signals of low priority for instance, and easily improve accommodation effectively using the resources in the apparatus.

Fourth embodiment

The OXC in the fourth embodiment uses the WDM technology for the OXC in the first embodiment to allow large-capacity light signal transmission to be performed.

FIG. 29 represents an overview of configuration of the OXC in the fourth embodiment. The OXC in the fourth embodiment has p (p is a natural number of 2 or more) pieces of light signal input terminals 200_1 to 200_p to which light signals having mutually different wavelength components λ_1 to λ_w multiplexed are inputted respectively, p pieces of light signal output terminals 201_1 to 201_p and $n \times m$ light SW202. Here, m is " $n + 1$." In addition, it has light amplifiers 203_1 to 203_p and wavelength separators 204_1 to 204_p corresponding to light signal input terminals 200_1 to 200_p respectively. Light

amplifiers 203₁ to 203_p amplifies light signals inputted from light signal input terminals 200₁ to 200_p respectively and supplies them to wavelength separators 204₁ to 204_p. Wavelength separators 204₁ to 204_p separates wavelengths per wavelength component $\lambda_1, \lambda_2, \dots, \lambda_3$ and have them inputted to any of n pieces of input port of n x m light SW202.

Furthermore, the OXC in the fourth embodiment has p sets of wavelength converters 205₁₋₁ to 205_{w-1}, 205₁₋₂ to 205_{w-2}, ..., and 205_{1-p} to 205_{w-p} for converting wavelengths of every w pieces of light signal outputted from n pieces out of m pieces of output port of n x m light SW202 into wavelength components λ_1 to λ_w respectively, wavelength multiplexers 206₁ to 206_p for multiplexing light signals having wavelength components λ_1 to λ_w converted by these p sets of wavelength converters, and light amplifiers 207₁ to 207_p for amplifying wavelength multiple light multiplexed by wavelength multiplexers 206₁ to 206_p respectively.

Furthermore, this OXC has DET 208 for detecting quality and management information of light signals outputted from the remaining one piece of output port of n x m light SW202, SV 209 for supervising quality and management information of light signals detected by DET 208, and CNT 210 for generating a control signal for changing path setting of n x m light SW202 based on supervising results of SV 209.

Description is omitted as to configuration and operation of n x m light SW202, DET 208, SV 209 and CNT 210 in the fourth

embodiment since they are the same as $n \times m$ light SW42, DET 43, SV 44 and CNT 45 in the first embodiment.

As for the OXC in the fourth embodiment of such configuration, light signals with wavelength components λ_1 to λ_w multiplexed transmitted from other offices (nodes) are inputted to light signal input terminals 200_1 to 200_p and optically amplified by light amplifiers 203_1 to 203_p . Light signals amplified by light amplifiers 203_1 to 203_p are separated per wavelength component by wavelength separators 204_1 to 204_p respectively and inputted to n pieces of input ports of $n \times m$ light SW202. $n \times m$ light SW202 can have n pieces of input port and m pieces of output port connected arbitrarily according to a control signal from CNT 210 similarly as $n \times m$ light SW42 in the first embodiment. Light signals inputted from light signal input terminals 200_1 to 200_p according to this path setting can be outputted from a desired output port.

Light signals outputted from output port numbers "1" to "m-1" of m pieces of output ports of $n \times m$ light SW202 are converted by w pieces into light signals of wavelength components predetermined by p sets of wavelength converters. Wavelength converters 205_{x-1} (x is 1 to w) converts them into wavelength components λ_x . Light signals converted into the wavelength components by wavelength converters 205_{1-1} to 205_{w-1} , 205_{1-2} to 205_{w-2} , ..., and 205_{1-p} to 205_{w-p} are multiplexed by w pieces by wavelength multiplexers 206_1 to 206_p . Multiplex light multiplexed by wavelength multiplexers 206_1 to 206_p are optically amplified by light amplifiers 207_1 to 207_p and

outputted from light signal output terminals 201_1 to 201_p , respectively. On that occasion, light signals inputted from any one input port are simultaneously outputted to two output ports in a connected state called a branch connection, where
5 one of them is outputted from an output port to which DET 208 is connected. Light signals inputted from each input port are outputted in order by a branch connection like this from an output port to which DET 208 is connected.

Light signals outputted from output port number "m" of
10 $n \times m$ light SW202 have light signal levels, optical SN ratio, OH and so on detected by DET 208 and are supervised by SV 209 as with the OXC in the first embodiment.

Thus, the OXC in the fourth embodiment separates them per wavelength component on the input side of $n \times m$ light SW202 by wavelength separators 204_1 to 204_p , and has them
15 simultaneously outputted to the predetermined output port and supervising port in a branch connection state at $n \times m$ light SW202. Any output port of $n \times m$ light SW202 other than the supervising port has wavelength multiplexers 206_1 to 206_p for
20 converting to predetermined wavelength so as to perform wavelength multiplexing here and output them from each light signal output terminal. Thus, it requires only one signal detecting means and only one supervising means for the purpose of supervising each of service signals similarly as the first
25 embodiment, and thus it allows the OXC apparatus to be rendered smaller-sized and lower-cost and also to easily correspond to large-capacity transmission using the WDM technology.

Fifth embodiment

While the OXC in the first to fourth embodiments supervise only light signals of one direction in which a light SW is transmitted, it is not limited thereto. The OXC in the fifth
5 embodiment accommodates light signals of both directions by using a light circulator.

FIG. 30 represents an overview of configuration of the OXC in the fifth embodiment. The OXC in the fifth embodiment has n pieces of upward light signal input terminals 220_1 to 220_n , n pieces of downward light signal output terminals 221_1 to 221_p , n pieces of upward light signal output terminals 222_1 to 222_n , n pieces of downward light signal input terminals 223_1 to 223_n and $m \times m$ light SW224. Here, m is " $n + 1$." In addition, the OXC in the fifth embodiment has light circulators
10 225_1 to 225_n provided corresponding to each of n pieces of input side port out of m pieces of input side port of $m \times m$ light SW224 and light circulators 226_1 to 226_n provided corresponding to each of n pieces of output side port out of m pieces of output side port of $m \times m$ light SW224. Here, it
15 is assumed that light circulators 225_1 to 225_n are provided corresponding to input side ports numbers "1" to " n " of $m \times m$ light SW224, and light circulators 226_1 to 226_n are provided corresponding to output side ports numbers "1" to " n " of $m \times m$ light SW224.
20

25 Light circulators 225_1 to 225_n are connected to upward light signal input terminals 220_1 to 220_n and downward light signal output terminals 221_1 to 221_n respectively in addition

to each input side port of $m \times m$ light SW224. Light circulators 225₁ to 225_n output light signals from upward light signal input terminals 220₁ to 220_n to each of input side ports numbers "1" to "n" of $m \times m$ light SW224, and output light signals from input side ports numbers "1" to "n" of $m \times m$ light SW224 to downward light signal output terminals 221₁ to 221_n.

Light circulators 226₁ to 226_n are connected to upward light signal output terminals 222₁ to 222_n and downward light signal input terminals 223₁ to 223_n respectively in addition to each output side port of $m \times m$ light SW224. Light circulators 226₁ to 226_n output light signals from output side ports numbers "1" to "n" of $m \times m$ light SW224 to upward light signal output terminals 222₁ to 222_n, and output light signals from downward light signal input terminals 223₁ to 223_n to output side ports numbers "1" to "n" of $m \times m$ light SW224.

In addition, on the remaining one piece each of input side port of input side port number "m" and output side port of output side port number "m" of $m \times m$ light SW224, the OXC in the fifth embodiment has DET 227, 228 for detecting quality and management information of light signals outputted from each port, SV 229 for supervising quality and management information of the light signals detected by DET 227, 228, and CNT 230 for generating a control signal for changing path setting of $m \times m$ light SW224 based on supervising results of SV 229.

Description is omitted as to configuration and operation of $m \times m$ light SW224 since its configuration and operation

are essentially the same as $m \times m$ light SW162 in the third embodiment although two-way light signals are transmitted. Description is omitted as to configuration and operation of DET 227, 228 and SV 229 since they are the same as DET 43 and SV 44 in the first embodiment.

Next, operation of OXC in such fifth embodiment will be concretely described by referring to FIG. 31.

FIG. 31 represents, as a concept, a branch connection state in the OXC in the fifth embodiment. However, as to the portions that are the same as the OXC shown in FIG. 30, the same symbols are given and description is omitted. Here, it is assumed that path setting is performed so that the first service signal inputted from an input side port of input side port number "1" of $m \times m$ light SW224 is outputted from an output side port of output side port number "2" of $m \times m$ light SW224. To be more specific, light signals inputted from upward light signal input terminal 220₁ are outputted by a circulator 225₁ to an input side port of input side port number "1" of $m \times m$ light SW224, and then path switching is performed so as to be outputted from an output side port of output side port number "2". Light signals outputted from an output side port of output side port number "2" of $m \times m$ light SW224 are outputted by light circulator 226₂ to upward light signal output terminal 222₂. Also, light signals inputted from downward light signal input terminal 223₂ are outputted by a circulator 226₂ to an output side port of output side port number "2" of $m \times m$ light SW224, and then path switching is performed so as to be outputted

from an input side port of input side port number "1". Light signals outputted from an input side port of input side port number "1" of $m \times m$ light SW224 are outputted by a circulator 225₁ to downward light signal output terminal 221₂.

5 In the case where this OXC has upward service signal 231 inputted from upward light signal input terminal 220₁ to be supervised, path setting is performed for $m \times m$ light SW42 by CNT 230 so that upward service signal 231 is simultaneously outputted from output side port numbers "2," "m" of $m \times m$ light
10 SW224 (branch connection state). Likewise, in the case where downward service signal 232 inputted from downward light signal input terminal 223₂ is to be supervised, path setting is performed for $m \times m$ light SW224 by CNT 230 so that downward service signal 232 is simultaneously outputted from input side
15 port numbers "1," "m" of $m \times m$ light SW224 (branch connection state).

 This branch connection state allows an upward service signal to be outputted from upward light signal output terminal 222₂, and also allows quality and management information of
20 the upward service signal to be detected at DET 228 and supervised at SV 229. Likewise, it allows a downward service signal to be outputted from downward light signal output terminal 221₁, and also allows quality and management information of the downward service signal to be detected at
25 DET 227 and supervised at SV 229. Thus, if supervising of the upward service signal or downward service signal is completed,

CNT 230 changes paths of $m \times m$ light SW224 so as to make the next service signal a subject of supervising.

Thus, the OXC in the fifth embodiment has light circulators 225₁ to 225_n, 226₁ to 226_n and DET 227, 228 provided on the input side ports and output side ports of $m \times m$ light SW224 so as to transmit both upward and downward service signals and also have quality and so on of each service signal supervised in a branch connection state. Thus, as for two-way light signals, even in the case where there are a plurality of service signals to be supervised passing through the OXC, it requires only one signal detecting means and only one supervising means for the purpose of supervising the service signals in each direction, and it allows the OXC to be rendered smaller-sized and lower-cost.

As described above, according to the present invention, supervision is performed one by one in a branch state even when there are a plurality of service signals to be supervised passing through the apparatus, it requires only one signal detecting means and only one supervising means for the purpose of supervising the service signals, and thus it allows the apparatus to be rendered smaller-sized and lower-cost. It is also possible to supervise not only the service signals not to be supervised but also the service signals to be supervised without influencing the quality.

In addition, according to the present invention, a branching ratio between light signals to be supervised inputted in the light signal supervising means and signals outputted

from the other second ports can be changed so that even if the levels of light signals to be supervised become lower, the levels of light signals to be originally transmitted become correspondingly higher, and thus it allows an optical
5 cross-connect apparatus of high reliability with a supervising function to be provided.

Moreover, according to the present invention, they are outputted as-is like other light signals when supervising is not performed, so it can accommodate service signals of low
10 priority for instance, and easily improve accommodation by effectively using the resources in the apparatus.

Furthermore, the present invention allows the apparatus to be rendered smaller-sized and lower-cost and also to easily support large-capacity transmission using the WDM technology.

15 In addition, the present invention allows management information placed in an overhead section of a predetermined frame format to be detected and supervised so that it can be easily applied to the existing network systems such as SDH and SONET.

20 Furthermore, according to the present invention, as the paths of the light switch means are branched per port in order, the optical cross-connect apparatus can supervise light signals inputted from any port one by one and in simple configuration with one detecting means and one supervising
25 means for supervising light signals even in the case where the apparatus becomes large-sized with additional ports.

Moreover, according to the present invention, as to
two-way light signals, even in the case where there are a
plurality of service signals to be supervised passing through
the apparatus, it requires only one signal detecting means
5 and only one supervising means for the purpose of supervising
the service signals in each direction, and thus it allows the
OXC apparatus to be rendered smaller-sized and lower-cost.
